Title:
Pancreatic cancer detected with 18F-FDG PET/CT in a case of IgG4-related disease

Dear Editor,

We present the case of a 67-year-old male who presented with severe abdominal pain, laboratory tests revealed IgG levels of 63.5 g/L, IgG4 levels of 63.7 g/L, and negative results for ANCA (anti-neutrophil cytoplasmic antibodies), Hematuria immunofixation electrophoresis, as well as the Cold globulin qualitative test. $^{18}$F-FDG PET/CT revealed multiple lesions with increased metabolism in the submaxillary saliva gland, intrahepatic bile ducts, prostate, seminal vesicle glands and the body of the pancreas. In addition, a circular cystic-solid lesion with metabolic heterogeneity was observed in the head of the pancreas, accompanied by visible dilatation of the
pancreatic duct (Fig. 1 A-E). Diagnostic imaging suggested IgG4-related disease (IgG4-RD), while pancreatic malignancy could not be definitively ruled out. The patient underwent fine-needle aspiration (FNA) biopsies of lung nodules and the prostate gland, all of which were consistent with the diagnosis of IgG4-RD (Fig. 1 F-G). Additionally, FNA biopsy of a pancreatic lesion was consistent with the diagnosis of pancreatic ductal adenocarcinoma.

IgG4-RD is a group of autoimmune diseases with an unknown etiology. It is characterized by tissue and organ infiltration by IgG4-positive plasma cells and elevated levels of serum IgG4 (1). IgG4-RD is characterized by multiple organ involvement, most frequently affecting the pancreas, bile ducts, salivary glands, lacrimal glands, kidneys, retroperitoneum and lungs. Patients with IgG4-RD are more prone to developing malignancies compared to the general population and are associated with deficiencies in immune surveillance. The inflammatory state of autoimmune pancreatitis (AIP) can induce pancreatic malignant tumors. Therefore, it is crucial to differentiate AIP from pancreatic cancer (2). \(^{18}\)F-FDG PET/CT has become a widely used method for evaluating IgG4-RD (3,4). AIP represents the pancreatic manifestation of IgG4-related disease. Typical imaging features show a 'sausage-like' enlargement of the pancreas with a “capsule-like” rim, accompanied by narrowing of the main pancreatic duct. On PET/CT images, AIP usually exhibits diffuse pancreatic uptake and lower SUVmax values than pancreatic cancer. IgG4-RD patients with focal masses in the pancreas should be carefully followed for early detection of complicating malignancies. Distinguishing between these two entities is crucial to prevent unnecessary pancreatic resections (5). In cases where patients exhibit multiple organ involvement with highly suspicious or pathologically confirmed IgG4-RD, and limited lesions are detected prior to immunosuppressive therapy, FNA biopsy pathology should be performed whenever possible to clarify the diagnosis and exclude a malignant tumor.

References

**Fig. 1.** $^{18}$F-FDG PET/CT showed multiple FDG-avid lesions in the maximum intensity projection image (A). Axial fusion images showed increased metabolism in the submaxillary saliva gland (B, SUVmax = 3.2, white arrows), intrahepatic bile ducts (C, SUVmax = 4.0, white arrows) and seminal vesicle glands (D, SUVmax = 5.9, white arrows). Axial CT, PET and fusion images showed a circular cystic-solid lesion and metabolic heterogeneity was observed in the head of the pancreas, accompanied by a visible dilatation of the pancreatic duct (E-G, SUVmax = 4.5, red arrows), with metabolic hyperintensities in the remaining pancreatic parenchyma (SUVmax = 3.1). Axial fusion images showed increased metabolism in the prostate (H, SUVmax = 12.3). Pathologic image of an FNA biopsy of a prostate lesion (I), with positive expression of IgG4 (J).
